KEY WORDS: Taxi trip data, activity space, residential community, land use classification, mobility patterns, O/D allocation

ABSTRACT:

There existing a significant social and spatial differentiation in the residential communities in urban city. People live in different places have different socioeconomic background, resulting in various geographically activity patterns. This paper aims to label the characteristics of residential communities in a city using collective activity patterns derived from taxi trip data. Specifically, we first present a method to allocate the O/D (Origin/Destination) points of taxi trips to the land use parcels where the activities taken place in. Then several indices are employed to describe the collective activity patterns, including both activity intensity, travel distance, travel time, and activity space of residents by taking account of the geographical distribution of all O/Ds of the taxi trip related to that residential community. Followed by that, an agglomerative hierarchical clustering algorithm is introduced to cluster the residential communities with similar activity patterns. In the case study of Wuhan, the residential communities are clearly divided into eight clusters, which could be labelled as ordinary communities, privileged communities, old isolated communities, suburban communities, and so on. In this paper, we provide a new perspective to label the land use under same type from people’s mobility patterns with the support of big trajectory data.

1. INTRODUCTION
The daily activity space of individuals directly shed a light on people’s lifestyle, the quality level of living, and as well as individual preferences. People live in different places may have different mobility patterns out of both geographical and socioeconomic reasons. The variation of activity space between people of different social groups or living in different residential communities reveals important aspects of social separation and isolation, thus has gained rising attention by city planner and policy makers in recent years (Wang et al. 2012).

Significant differences are found in the usage of time and space between individuals of different social groups. Zhou & Deng (2010) found that people from different classes have different spatio-temporal patterns according to a household survey involved 800 families in Guangzhou. For example, people from lower class have small activity space around the inner city or around their residential communities, while people from upper class have more time spending on outdoor activities and the travel space is much wider. Zhang & Chai (2011) focused on the middle and low income groups in Beijing, and found that their daily activity patterns show a trend of fragmentation in time and disparity in space.

In the development of urbanization and prosperity of commodity housing in Chinese cities, the economic status has become a determining factor resulting the residential segregation (Wu 2002). The commercial development accelerates sociospatial differentiations when people are able to choose where to live regarding to their social background. A direct consequence is that people from the same social class gathered to live in same community consciously. Wang et al. (2012) grouped three typical enclaves existed in current Chinese cities according to the social composition of residents: institutionally privileged enclaves, economically privileged enclaves, and ordinary neighbourhoods. By identifying three prespecified sample areas, they found that people live in these three types of communities not only share differences in place of residence, but also separate from each other at activity space. Zhang et al. (2014) had similar findings using family survey data in Beijing. These research further extend the differentiation of activity space happened on individuals to communities at a collective level.

With the support of big geo-data, to get the characteristics between locations under different land use classification or even on the same land use type from the spatial interaction and mobility patterns have drawn rising attentions in recent studies. Liu et al. (2016) proposed an unsupervised land use classification method by grouping the spatial interactions between parcels using taxi trip data in Shanghai. Kong et al. (2017) focused on the classification of public facilities, such as hospitals, using the mobility interactive patterns of visitors extracted from taxi data. They found that people from different classes have different spatio-temporal patterns at a collective level, we highlight the spatial distributions of residential communities of different types in different areas in Wuhan. Secondly, land use type data is usually not hard to achieve for city planners. Detailed information inside the same land use type, for example what differences lie in residential communities in the whole city, are more valuable but always hard to label. By focusing on residential communities in this paper, we provide a new perspective to label the land use under same type from people’s mobility patterns when lacking of other source data.

The contributions of this study are two folds. Firstly, by grouping the residential communities with similar activity patterns at a collective level, we highlight the spatial distributions of residential communities of different types in different areas in Wuhan. Secondly, land use type data is usually not hard to achieve for city planners. Detailed information inside the same land use type, for example what differences lie in residential communities in the whole city, are more valuable but always hard to label. By focusing on residential communities in this paper, we provide a new perspective to label the land use under same type from people’s mobility patterns when lacking of other source data.

The remainder of this paper is organized as follows: section 2 briefly describes the study area and data used in this research; section 3 presents how we measure the aggregated activity patterns in residential community using taxi trip data; the result of the case study is reported in section 4; finally we draw our conclusions and discuss the future work in section 5.

2. STUDY AREA AND RESEARCH DATA

2.1 Study area
As the largest city in central China, Wuhan is divided into three cities, Wuchang, Hankou, and Hanyang by Yangtze River and its branch Han River. The central districts of Wuhan has 7 districts covering 888km² in total and the main urban area inside the 3rd ring expressway is 520km². The per capita net floor space of urban residents in 2012 is 33.5m² (The Wuhan Statistical Bureau, 2013).

2.2 Data description
The case study in this paper uses the GPS trip data of over 10,000 taxis in Wuhan for four weekdays (from 9/7–9/14/2012, with 9/11 and 9/12 missing). The trip dataset is obtained after map matching and GPS trajectory reconstruction process, containing the taxi ID, geographical coordinates and stamp time of both pick-up point (referred as Origin of the trip and denoted as \( P_i^0 \) below) and drop-off point (referred as Destination of the trip and denoted as \( P_i^3 \)), trip travel time (denoted as \( t_{ii} \)) and trip travel distance (denoted as \( d_{ii} \)) in each trip record \( P_{ii} \). The land use data including 11 land use types in the main urban area of Wuhan, 2012, is mapped in Figure 1 below.
There are two rules to perform function $f(\cdot)$, the minimum distance rule and the distance decay rule. Under the minimum distance rule, the point is assigned to the nearest polygon, see equation (2). Under the distance decay rule, we assign the point according to the distance decay ratio, see equation (3). We'll discuss the effectiveness of the two rules later in the case study.

$$f(x) = \begin{cases} 1, & x = \text{min}(x) \text{ and } x < \text{walk\_dis} \\ 0, & \text{otherwise} \end{cases}$$

(2)

$$f(x) = 1 - \frac{x}{\text{walk\_dis}}$$

(3)

where $x$ is the distance $d(P_i, \text{location}_j)$ in equation (1).

The O/D points $P_i^0$ and $P_i^P$ are treated separately so as to differential the arrival and depart activities happened in different locations respectively. In this stage, every polygon with all land use types are involved when generate the candidate set, then we calculate $p(P_i \rightarrow \text{location}_j)$ for all locations.

### 3.2 Collective activity patterns

The residential communities are differential from each other at the level of how residents live in these communities use the urban space temporally and spatially. Here we use the activity patterns, including the activity volume, travel distance and travel time, and activity space at the aggregated level, to demonstrate how people travel differently.

Each land use polygon is treated as an activity location. For every location in the candidate set, we have $P_{\text{Set}}^\text{depart}$ and $P_{\text{Set}}^\text{arrive}$ to store all the trips depart from and arrive at it when $P_i$ is chosen as $P_i^0$ and $P_i^P$ in equation (1), respectively. The intensity $l_j$, weighted average travel distance $l_d_j$ and travel time $l_t_j$ of the trips belongs to location $j$ is defined as equations (4–6).

$$l_j = \sum_{P_i \in P_{\text{Set}}^\text{depart}} p(P_i \rightarrow \text{location}_j)$$

(4)

$$l_d_j = \frac{1}{n} \sum_{P_i \in P_{\text{Set}}^\text{depart}} p(P_i \rightarrow \text{location}_j) \text{dis}_i$$

(5)

$$l_t_j = \frac{1}{n} \sum_{P_i \in P_{\text{Set}}^\text{depart}} p(P_i \rightarrow \text{location}_j) \text{tt}_i$$

(6)

Standard distance proposed by (Bachi 1962) are proven to be effective when activity points are sparsely distributed. Here we take the mean point in the original equation as the central point of land use location, and the modified calculation is presented as (7):

$$sd_j = \frac{1}{n} \sum p(P_i \rightarrow \text{location}_j) \cdot xd$$

(7)

When depicting the daily activity space of an individual, the most widely used measurements are standard ellipse based on home and work place, standard circle, minimum convex polygon, standard distance ellipse (SDE), and kernel densities (Schönhöfer & Axhausen 2003), as shown in Figure 3. By constructing a smallest possible ellipse to cover the activities with a certain probability (e.g. 95%), the standard distance ellipse is a most commonly accept measurement of activity space of an individual person when the home or work location is unknown. Here we adopt the area of standard distance ellipse, which is denoted as area$_{SDE_j}$, to represent the activity space at the collective level inside a residential community, see equation (8).
\[ \text{area}_{SDE_j} = \text{area} \left( SDE\left( PSet_j \right) \right) \]  

(8)

Therefore, for every location, we have a ten dimension vector from equations (4 – 8) to depict all the arriving and departure activity patterns.

3.3 Clustering by collective activity patterns

The agglomerative hierarchical clustering algorithm is a bottom-up algorithm because it does not require any prespecified number of clusters. It treats each observation as a singleton cluster at the first step, and then merge pairs of clusters successively considering the similarity until all clusters are agglomerated into one big cluster containing all observations. The algorithm detail could be referred in (Han et al. 2011). By only keeping the residential land use type, we employ the agglomerative hierarchical clustering algorithm to cluster the residential communities with similar activity patterns.

4. RESULTS

4.1 O/D allocation

In the O/D allocation process, we set \( \text{walk}_{dis} = 200 \text{m} \), which is the same as the walking distance used for taxi passengers in Kong et al. (2017), to create the buffer around the taxi pick-up and drop-off locations. Then we calculate the activity intensity of each land use parcel all over the city. Figure 4 shows an example of the geographical distribution of depart activity intensity in 9/7/2012. When adopting the minimum distance rule (see Figure 4(a)), there are a lot of land use polygons have particularly low intensity or even none trips, especially in areas close to the third ring. The distribution of the intensities is quite uneven, which results in a problem that the larger the area of the polygon, the higher the intensity is. This is because the minimum distance allocation does not take the GPS errors and human behaviour randomness into account.

The results of distance decay rule (as shown in Figure 4(b)) performs better and makes more sense than the minimum distance rule. The areas with highest intensity are the business centers inside the city, such as Wuguang, Jiedaokou, Wangjiadun, and Guanggu. Apart from that, the three railway stations also attract high density of trips. Compared to residential communities, public facilities such as universities show a high intensity of activities taken by taxi. This is because the fall term always starts in the early September in universities, there is a high possibility that students and parents take taxies to depart from or arrive at universities. Hankou district has the more activity hotspots than the other two districts, while Hanyang district has the lowest visiting intensity by taxi.

4.2 Clustering patterns of residential communities

The hierarchical clustering tree is plotted as Figure 5. We take the value at the red line to cut the tree and finally get 8 clusters, from C1 to C8. The statistical values and the spatial distribution of the clustering results are mapped in Figure 6 and Figure 7 respectively. The C0 in Figure 7 is marked as errors. It is easy to notice that the rising and falling patterns in arriving activities shares a lot of similarity with the departure activities in between different clusters, see Figure 6. There are more arriving activities than departure activities, and the distance of arriving activities are a bit higher than the departure activities. This implies that people tend to take taxi back home than to...
The two activity space measurements, i.e. $sd_j$ and $area_{SDE}$, have a very similar tendency in each cluster, which means that the two indices have almost same effects when depicting activity space patterns. The average value of travel distance $t_{d_j}$ and travel time $t_{t_j}$ between each cluster have little differences also.

Figure 5. The hierarchical clustering tree and the cut line (red).

Most residential communities belong to C1 and C3, which could be classified as ordinary communities. The $sd_j$ and $area_{SDE}$ in C3 are slightly larger than in C1. The residents live in these communities are mainly middle class householders. Among the eight clusters, the C8 cluster has the lowest activity intensity $I_{ij}$, which only contains four residential communities located near the boundary of the main city. The travel cost and activity space are the highest in C5, in which the residential communities are distributed in the suburban. The geographical factor such as lakes have huge impact on the travel patterns of residents living in this cluster. Although communities in C5 and C8 are both located in the margin of the city, people live in communities in C5 have much higher travel cost, which implies a lack of efficient transportation vehicles around these areas. The communities in these two clusters could be labelled as suburban communities.

Compared to ordinary communities, the intensity $I_{ij}$ of C2 are lower than that of C1 and C3, while the activity space (both $sd_j$ and $area_{SDE}$) are larger. This implies that taxi is not an always choice for people living in C2, but whenever they travel by taxi, they are likely to go to a remote place. There is a high possibility that people live in communities of this cluster have a high ownership of private car, hence they are little dependent on taxis for travel. And they are probably have a high income level that the taxi fee is not a foremost factor when making choices. We identify communities in C2 to be privileged communities, including the institutionally privileged communities that located inside or beside the government bureaus/institutions, such as dependent’s area of Wuhan University, and economically privileged communities such as Lidao Garden community.

Figure 6. Statistical values of the clustering patterns

In contract with C2, the resident in C4 are very old communities or communities under demolition, which have very low intensity $I_{ij}$ and small activity space. Therefore, the communities in C4 are labelled as old isolated communities. Compared to C4, C6 and C7 have higher activity space, but moderate intensity. Further survey is needed to label the communities in these two clusters precisely.

Above all, the analysis results show that people live different places vary significantly in terms of activity patterns. The activity patterns including intensity, travel cost, and activity space are useful when labelling the different characteristics of residential communities. The huge differences between the eight clusters provide another evidence that there exists a significant social classification in the resident space inside the urban.

Figure 7. The geographical distribution of eight clusters of residential communities.

5. CONCLUSIONS AND FUTURE WORK

The prevalent of big trajectory data has provide us a more efficient way to track urban movement and activity patterns. In this paper, we studied about the activity patterns in different residential communities derived from taxi trip data. By grouping the residential communities with similar activity patterns at a collective level, we highlight the spatial distributions of residential communities of different types in different areas in Wuhan. The residential communities are clearly divided into eight clusters, which could be labelled as ordinary communities, privileged communities, old isolated communities, suburban communities, and so on. The results show that people’s activity patterns in different residences are highly related to the geographical and socioeconomic attributes of communities. The methodology in this paper provides us a new way to get the different characteristics of residential communities in a city according to their mobility patterns by taxi. Furthermore, the method proposed in this paper could be
used to label the land use under same type (i.e. residential) from people’s mobility patterns when lacking of other source data.

In the future work, we will further look into the differences in each residential community regarding the temporal patterns of activities, such as when the activity happens and how does the activity change across time during a day. Additionally, we will incorporate the spatial interactions between locations in order to learn more about how different residential groups share their time as well as usage of urban space.
